Keywords: Carbon dioxide, Organic fertilization, Drought, Soil

Carbon mineralization is the phenomenon where organic carbon forms are converted to carbon dioxide (CO₂) which is then released to the surrounding environment. Many factors can affect carbon mineralization such as drought conditions and organic material composting stage. This experiment aims to investigate the effect of different manure application levels in addition to different water availability levels on CO₂ mineralization in calcareous soil over time. For this purpose, different mixed manure inputs of (0%, 5%, and 10%) were added to airily dried calcareous soil samples and different water availability levels (40%, 50%, and 60%) were applied. CO₂ emissions were then monitored during an incubation period of 65 days 30 ± 2 °C. The results showed that by increasing organic matter input, CO₂ fluxes were increased during the incubation period to reach 198.55 mg/100g soil in 10% organic matter treatments after 50 days of incubation. Water availability appeared to have little to no influence over CO₂ emissions within the chosen experimental ranges. Furthermore, response surface model contours and fitted means factorial interaction plots of CO₂ emissions showed that the added organic matter underwent a severe mineralization activity since the first day of incubation. These results refer to the high carbon mineralization rates in calcareous soils under dry conditions, and the increased CO₂ emissions by increasing manure inputs refer to the importance of using more stable composted material rather than higher organic material inputs in this type of soil.

1. Introduction

Greenhouse gasses (GHGs) are mainly Methane (CH₄), Carbon dioxide (CO₂), and nitrous oxide (N₂O) gases that escape as a result of different activities and form a trapping layer for the omitted earth infrared radiation resulting in a warmer climate. The energy production sector holds the main share of GHGs emissions with 66.5% of the total generated GHGs, while on the other hand, agricultural production processes contribute with 13.5% of the total emitted GHGs [1]. Although soil with its organisms is considered a fundamental CO₂ reservoir; it was reported that 35%, 47%, and 53% of the total agricultural CO₂, CH₄, and N₂O emissions respectively are soil originated [2]. Therefore, with the international relentless pursuit to cut on GHGs emissions including those induced by agricultural practices, more studies are required to monitor GHGs fluxes of different agricultural production phases and under different conditions [3]

The organic matter is one of the main soil components and it contributes to improving the physical, chemical, fertile and biological characteristics of the soil. Organic matter is a mixture of plants, animals and microorganisms residues in different states of decomposition and stability. The organic substance in the soil was classified according to the degree of decomposition into easily decomposing forms such as simple sugars and proteins; slow decomposing

compounds such as cellulose And hemicellulose; and difficult to decompose such as lignins, waxes, chitin, and multiple phenols. Soils differ in their organic matter content depending on vegetation, climate, and agricultural exploitation; as this content is less than 0.1% in desert soils and 100% in peat soils [4].

Carbon mineralization is the process where organic carbon is converted into carbon dioxide (CO₂) under the effect of soil microorganisms [5][6][7]. This phenomenon not only constantly minimizes the organic matter content in the soil but also imposes great hazards to the environment taking into consideration the huge amounts of CO₂ escaping to the atmosphere especially under drought conditions and poor soil structure [8]. One of the most common methods for estimating the organic decomposition in the soil is measuring the amount of carbon dioxide released from organic matter during an incubation period and under standard conditions [9][10]. All the organic matter that is added to the soil undergoes a breakdown process by soil organisms and then respire as CO₂ while the rest of it is synthesized into other more stable forms as it is reported that 60-80% of the remaining stabilized organic matter is humus [11].

Water stress occurs as a result of soil water availability shortages, resulting in plant growth disruption and an overall production decrease [12]. Various methods have been used to induce efficient tolerance to water stress and to enhance nutrients availability under water stress conditions such as the use of beneficial microorganisms; the addition of organic matter and nutrients; the use of chemicals such as proline, silicon, and Osmoprotectants [13]. Although organic matter plays a vital role in enhancing chemical and physical properties in soils including water stress tolerance, the fast mineralization of organic material under dry conditions is considered a major environmental setback [14]. Therefore, this study aimed to investigate the effects of different amounts of organic manure inputs under different levels of water stresses on CO₂ emissions over time.

2. Materials and Methods

2.1. Soil and manure properties

Soil and manure mixture (cows, sheep and poultry manure mixture 1: 1: 1) chemical and physical properties were determined by the methods provided in [15] and the results of the analysis are shown in (Table 1 and 2) respectively.

2.2. Experimental materials and levels

The soil was aeri ally dried and 100 g samples were weighed. Three levels of manure (0, 5, and 10% of the soil weight) were applied. The added manure was then mixed well with the soil and the formed mixtures were then transferred to plastic bottles with airtight septa. After that, three levels of water stress were applied by adding different amounts of water (40, 50 and 60% plant-available water capacity). The bottles were then incubated under a temperature of 30 ±2 °C for a period of 65days, and the amount of carbon dioxide released from the soil was estimated after 0, 2, 5, 7, 13, 16, 31, 50, and 65 days of incubation. The lost water was compensated by registering the weights of the bottles and adding water according to the loss in weight. Experiment levels are shown in (Table 3).

Table 1. The chemical and physical characteristics of the soil used in the experiment

Characteristics	Value	Unit		
pH (1: 1)	7.56	-		
Electrical Conductivity EC (1: 1)	3.13	dS m ⁻¹		
Organic matter (OM)	1.8			
Carbonate minerals	20.35	%		
Gypsum	0.52			
Cation exchange capacity (CEC)	25.1	cmol+ kg ⁻¹		
Concentration of dissolved ions	Calcium	8.38		
	Magnesium	6.01		
	Sodium	4.95		
	Potassium	0.45	mmol L ⁻¹	
	Chloride	12.01		
	Sulfate	7.7		
	Carbonate	-		
Bicarbonate	4.75			
Available nutrients	Nitrogen	34.16		mg kg ⁻¹
	Phosphorus	12.59		
	Potassium	160.97		
	Iron	2.72		
	Zinc	1.82		
Soil texture	Manganese	2.8	%	
	Sand	16		
	Silt	52		
Physical characteristics	Clay	32	g cm ⁻³	
	Bulk density	1.4		
	Field capacity	0.39		
	permanent wilting point	0.17		cm ³ cm ⁻³
available water capacity	0.22			

2.3. Released CO₂ measurement

Released CO₂ was estimated based on [16] method. 20 mL of sodium hydroxide (1 N) was added to the air-tight bottles used in the experiment through the bottle's septum, as CO₂ reacts with sodium hydroxide and produces sodium carbonate. Then, by adding drops of barium chloride solution 50% to form barium carbonate as seen in the following equations:

After that, the formed barium carbonate was titrated against 0.5 N of hydrochloric acid, using phenolphthalein as a reaction endpoint indicator. CO₂ was then estimated using the following equation:

$$\text{Released CO}_2 \text{ mg/100 g soil} = (\text{B}-\text{V}) \text{ NE}$$

When B: Volume of the acid consumed (ml) in control titration.

V: Volume of the acid consumed (ml) in treatment titration.

N: Hydrochloric acid normality

E: the equivalent weight of CO₂ (22 g)

Table 2. The chemical and physical characteristics of the organic fertilizer mixture used in the experiment

Characteristics	Value	Unit
Organic carbon	310	
Total phosphorus	12.33	g kg ⁻¹
Total nitrogen	19.3	
Total potassium	18.34	
C/N	16.1	-
Total iron	388.4	
Total zinc	233.1	mg kg ⁻¹
Total manganese	284.5	
Calcium	10	mmol L ⁻¹
magnesium	5	
Humic acids	1.63	
Fulvic acids	0.196	%
Humic	6.831	
Organic matter	53.44	
Electrical Conductivity 5:1	30.25	dS m ⁻¹
pH 5:1	6.94	-
Density	0.43	g cm ⁻³

Table 3. Experiment levels in regards to the added organic matter and the applied water stress

Organic fertilization levels		Water stress levels	
Amount	Symbol	Amount	Symbol
Without organic matter (Control)	M0	40% of available water	S1
5% Organic matter	M1	50% of available water	S2
10% Organic matter	M2	60% of available water	S3

2.4. Statistical analysis

The experiment was carried out in a completely randomized experimental design with three replicates for each treatment at each evaluation. Means were compared using Tukey's least significant difference (LSD) test at a confidence level of $p=0.05$. Mean CO₂ fluxes heat map was constructed using GraphPad Prism 7 software. Contour plotting for CO₂ emissions and response surface analysis was carried out using Minitab 19 software.

3. Results and Discussion

Results have shown a significant increase in CO₂ emissions after 13 days of incubation and another increase was observed after 31 days even in control treatments without organic material additions (M0) and under all water stress conditions; however, CO₂ emissions in both 5% (M1) and 10% (M2) treatment were significantly higher than those of (M0) treatment and under all water availability treatments (S1, S2, and S3) with no significant differences in CO₂ levels between (M1) and (M2) (Fig. 1). These observations in M0 treatments are contributed to carbon mineralization in the already existed organic material in soil samples (Table 1) and the almost instantaneous increase in both (M1) and (M2) treatments (2-5 days after incubation) along with the additional increase later are attributed to the added manure. These results are similar to those obtained by [17] who reported that the addition of composted dairy manure caused a sudden increase in carbon mineralization mainly originated from the already present organic

matter. The highest observations were noticed in M2S2 treatment with CO₂ emission of 198.55 mg/100 g soil. The increasing trend in CO₂ emissions after organic matter application and overtime was previously reported by [18-22].

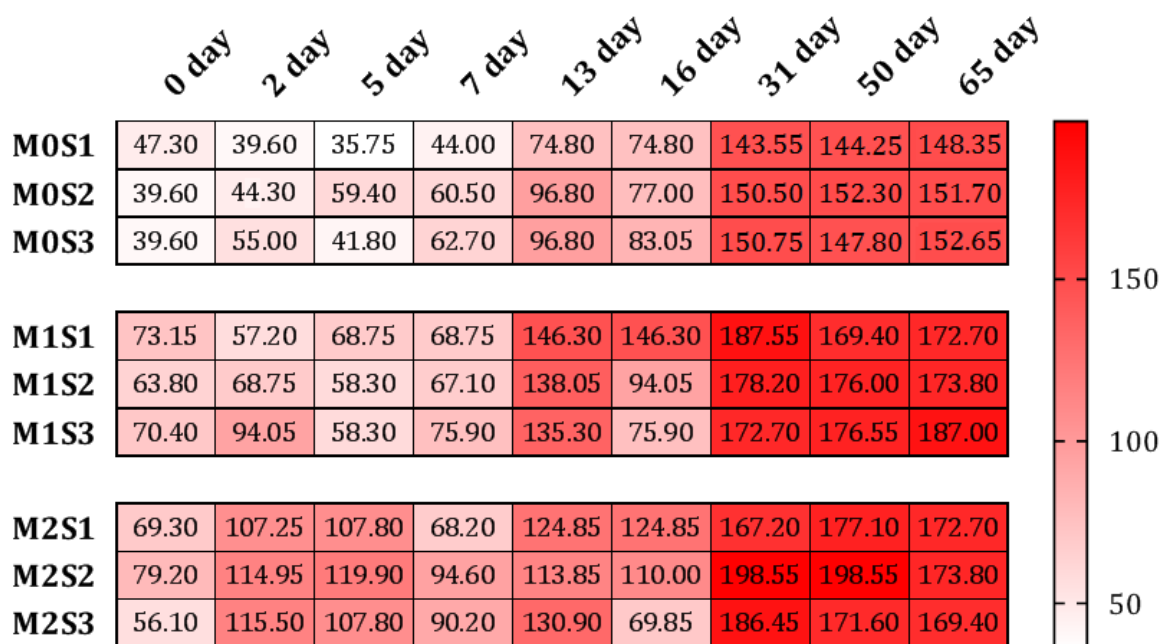

Figure 1. CO₂ emissions in calcareous saline soil under different organic material and water availability inputs through 65 days of incubation. M0, M1, and M2 refer to different organic material inputs (0, 5, and 10 %); S1, S2, and S3 refer to different available water content (40, 50, and 60 %). Tukey's LSD = 23.3 at $p=0.05$.

By fitting the data into a response surface design, original CO₂ flux data contour plots (Fig. 2 A, B, and C) showed high similarity to those of response surface contour plots (Fig. 2 D, E, and F). Evaluation day and organic matter interaction contour plot (Fig. 2 A) illustrated that regardless of water availability, soil underwent two sharp peaks of CO₂ emissions with M1 treatments one of which after 30 days of incubation and the other after 60 days. On the other hand, those two peaks were substituted with a plateau of CO₂ emission under M2 treatments while no sharp flux was noticed under M0 treatments (Fig. 2 A). However, response surface analysis showed that CO₂ flux plateau extended to include M0 treatment after 50 days of incubation (Fig. 2 D). Fixing the manure input has shown a similar C mineralization behavior between all three water availability treatments (S1, S2, and S3) throughout incubation period with a CO₂ flux lower than 175 mg/100g soil during the first 30 days of incubation and higher during the following days (Fig. 2 B and E). Interestingly, the relation between different organic material and available water levels was less complicated with only three grades contour plot (Fig. 2 C). CO₂ fluxes appeared to decrease either by decreasing organic matter input (M0) or by increasing water availability (S3) while on the other hand, the highest emission levels were observed with high organic matter and low available water treatments (Fig. 2 C and F). The increased CO₂ fluxes observed when higher levels of organic matter were applied (Fig. 2 A and D) were also reported by [23] who observed an increase in CO₂ emissions by increasing compost input of different sources; however, our results showed an even more increase throughout time which is contributed to the used manure in the current experiment which had much less composting stable profile.

Figure 2. Contour plotting for CO₂ emissions in calcareous saline soil under different organic matter inputs and during the incubation period (**A and D**); different water availability and during the incubation period (**B and E**); and different organic material and water availability inputs (**C and F**). (**A, B, and C**) represent raw data contour plotting while (**D, E, and F**) represent response surface contour plotting

Fitted means factorial interaction plots of CO₂ emissions were obtained (Fig. 3). Organic matter and water availability interaction plot showed that different levels of water availability had an almost identical CO₂ flux (Fig. 3 A). Furthermore, water availability and evaluation day interaction plot showed that different water levels had no effect on CO₂ emission for the same evaluation period (Fig. 3 C). These observations indicated that there was little to no effect contributed to water availability levels (S1, S2, and S3) on CO₂ flux within the different other dimensions of the model (time and added organic material). Water availability treatments used in the current experiment (40%, 50%, and 60%) did not induce significant differences in CO₂ fluxes under experiment condition; however, it was previously reported that increasing water levels to reach 100% of field capacity had significantly increased CO₂ emissions when compared to CO₂ fluxes under 70% of field capacity after 90 days of compost application for both sand and silt-clay soils [8]. Furthermore, [19] previously reported a dramatic increase in CO₂ fluxes after re-wetting dry soils of high organic content. An increasing trend in CO₂ emissions by increasing manure input was observed directly after organic material application (day 0) as can be seen in (Fig. 3 B) and the most dramatic increase in CO₂ fluxes was observed during the first month of incubation (Fig. 3 B and C) which is similar to [17]. Therefore, to increase the stability of

organic matter in dry soils, more stable organic sources rather than higher organic matter inputs should be used [18][23-25].

4. Conclusions

It is obvious that CO₂ emissions in calcareous soil due to organic matter mineralization under drought conditions are already high and increase throughout time. Additionally, CO₂ fluxes increase by increasing manure inputs and this increase is more dramatic during the first 30 days of application regardless of water availability conditions. These results refer to the importance of using more stable composted material rather than higher organic material inputs in this type of soil.

Conflict of interest statement

The authors declared no conflict of interest.

Funding statement

The authors declared that no funding was received in relation to this manuscript.

Data availability statement

The authors declared that all related data are included in the article.
